Viability

Reason for Discrepancies in Identifying Myocardial Viability by Thallium-201 Redistribution, Magnetic Resonance Imaging, and Dobutamine Echocardiography

José Zamorano, MD, Juan Delgado, MD, Carlos Almería, MD, Raúl Moreno, MD, Miguel Angel Gómez Sánchez, MD, José Luis Rodrigo, MD, Cristina Fernández, MD, Joaquin Ferreiros, MD, Juan José Rofilanchas, MD, and Luis Sánchez-Harguindey, MD

Dobutamine echocardiography (DE), magnetic resonance imaging (MRI), and thallium redistribution (TS) are used to assess cardiac viability. However, these modalities sometimes yield contradictory results. Our aim was to establish the degrees of agreement among DE, MRI, and TS in identifying myocardial viability and to analyze the minimum critical mass of live (viable) cells required for each test to identify viability. A prospective study was done in which DE, MRI, and TS were consecutively performed in 10 ischemic patients scheduled for heart transplantation. The explanted heart was analyzed to quantify the amount of live cells per segment. The pathologic data were compared with the test results to analyze the minimum mass of viable cells required by each technique to identify viability. Mean age was 58 ± 8 years (8 men). The mean ejection fraction was 0.27 ± 0.04 . Seven patients had severe cardiac failure (New York Heart Association functional class IV) and 6 patients had refractory angina. A total of 150 cardiac segments were analyzed. Among the 150 segments, 107 (71.3%) showed some degree of myocardial necrosis. Mean total area, mean fatty area, and mean necrotic area per segment were 2.53 ± 0.7 , 0.13 ± 0.2 , and 0.55 ± 0.5

cm^2 , respectively. As expected, a higher amount of necrotic tissue was found in nonviable segments. From the 150 segments, DE identified 90 as viable and 60 as nonviable. These data were similar to that of MRI (98 viable and 52 nonviable). A higher proportion of viable segments was found by TS (117 viable vs 33 nonviable). The concordance between DE and TS was only moderate (κ 0.49). The agreement between MRI and TS also showed moderate concordance (κ 0.56). The highest agreement was found between DE and MRI (κ 0.73). Thus, discrepancies in assessing viability by DE, MRI, and TS may be due to differences in the minimum critical mass of live myocytes required by each technique to diagnose viability. Thallium requires a lesser amount of live tissue than DE or MRI to detect viability; also, its maximum diagnostic efficiency is obtained with lesser amounts of live tissue on each segment. These considerations should be taken into account when these diagnostic tests are used for the detection of viability before revascularization procedures. ©2002 by Excerpta Medica, Inc.

Identification of Stunned Myocardium With Parametric Imaging-Based, Quantitative Myocardial Contrast Echocardiography After Acute Myocardial Infarction

Viviana Serra, MD, Leopoldo Perez de Isla, MD, Maria Perez Ferro, MD,

Microvascular integrity demonstrated by myocardial contrast echocardiography (MCE) predicts functional recovery after an acute myocardial infarction (AMI). Recently, parametric imaging-based quantitative MCE has been developed. Our aim was to assess the usefulness of parametric imaging-based quantitative MCE parameters to predict the functional recovery of akinetic segments after primary percutaneous transluminal coronary angioplasty (PTCA). Fifty-three consecutive patients with a first AMI were enrolled. They underwent primary PTCA. Standard echocardiography and real-time MCE were performed. Qualitative analysis and parametric imaging-based quantitative parameters were measured offline by different blinded investigators. Dobutamine stress echocardiography was performed 1 month later. A new standard echocardiogram to assess the functional status of the akinetic segments and coronary angiography to evaluate the presence of restenosis at the level of the culprit lesion were performed 6 months later. The mean patient age was 62.9 ± 14 years, and 42 were men (79%); 170 segments were akinetic. Of these, 105 (62%) recovered their function. The best parameter to predict functional recovery was the myocardial blood flow velocity (β). These results were better than those obtained using dobutamine stress echocardiography and qualitative MCE to predict functional recovery. In conclusion, parametric imaging-based quantitative MCE is an accurate diagnostic tool to detect stunned myocardium after AMI. Its diagnostic accuracy in predicting the functional recovery of akinetic segments after primary PTCA is better than the accuracy of dobutamine stress echocardiography and qualitative MCE. © 2005 Elsevier Inc.
